Abstract

We introduce the Multi-Inter-Distance constraint that ensures no more than \( m \) variables are assigned to values lying in a window of \( p \) consecutive values. This constraint is useful for modeling scheduling problems where tasks of processing time \( p \) compete for \( m \) identical resources. We present a propagator that achieves bounds consistency in cubic time. Experiments show that this new constraint offers a much stronger filtering than an edge-finder and that it allows to solve larger instances of the runway scheduling problem.

Introduction

Constraint solvers offer many ways to model scheduling problems. The constraint All-Different (Régis 1994) ensures that at most one task starts at a given time. When there are \( m \) resources, the GCC (Régis 1996) limits the number of tasks starting at a given time to \( m \). These two constraints are useful when tasks have a unit processing time. When processing times are greater than one unit, the Inter-Distance (Artiouchine & Baptiste 2005; Quimper, López-Ortiz, & Pesant 2006) constraint makes sure that the starting times are at least \( p \) units of time apart. When processing times differ for each task, the Cumulative (Mercier & Hentenryck 2008; Vilím 2009) constraint allows to model this situation. All constraints, except the Cumulative constraint, offer a complete filtering of the release times and deadlines of the task in polynomial time. This filtering is NP-Hard for the Cumulative constraint. However, there exists no filtering algorithm that prunes the release times and deadlines when the processing time of each task is \( p \) and when there are \( m > 1 \) resources. We introduce the Multi-Inter-Distance constraint and its first filtering algorithm achieving bounds consistency. This constraint complements the offering of constraint solvers. We show that this constraint is very efficient to solve problems such as the runway scheduling problem.

The Multi-Inter-Distance Constraint

The Multi-Inter-Distance constraint limits the number of variables assigned in a window of \( p \) consecutive values to \( m \). Definition 1 formally presents the constraint.

Definition 1 Multi-Inter-Distance([\( X_1, \ldots, X_n \)], \( m, p \)) is satisfied if and only if at most \( m \) variables \( X_i \) are assigned to a value in any window of \( p \) consecutive values. More formally, we have the following logical identity.

\[
\forall v \ | \{i \ | \ X_i \in [v, v+p)\}| \leq m
\]

The Multi-Inter-Distance is a generalization of well known constraints. When \( p = 1 \) and \( m = 1 \), the Multi-Inter-Distance constraint specializes into an All-Different constraint. When \( p = 1 \) and \( m > 1 \), the Multi-Inter-Distance encodes a GCC where each value can be assigned to at most \( m \) variables. Finally, with \( m = 1 \) and \( p > 1 \), the Multi-Inter-Distance becomes an Inter-Distance constraint. On the other hand, the Multi-Inter-Distance constraint is a specialization of the Cumulative constraint. Each variable can be seen as the starting time of a task that consumes one unit of resource during a period of time \( p \) where the cumulative capacity of the resources is \( m \).

Two results emerge from these relations among the constraints. Since it is NP-Hard to enforce domain consistency on the Inter-Distance constraint (Artiouche, Baptiste, & Dür 2004), it is necessarily NP-Hard to enforce domain consistency on the Multi-Inter-Distance. Because the edge-finder (Mercier & Hentenryck 2008; Vilím 2009) does not enforce bounds consistency on the Inter-Distance (Artiouche & Baptiste 2005), it does not enforce bounds consistency on the Multi-Inter-Distance either.

We show how to detect feasibility of the Multi-Inter-Distance constraint in quadratic time. We then show how bounds consistency can be enforced in cubic time.

General Background

We consider constraint satisfaction problems where variables are assigned to integer values. The domain of a variable \( X_i \) is denoted \( \text{dom}(X_i) \). We assume that the domain of a variable \( \text{dom}(X_i) = [l_i, u_i) \) is a semi-open interval where \( l_i \) and \( u_i \) are called the lower bound and upper bound of the domain. The value of the variable \( X_i \) must be greater than or equal to \( l_i \) and must be strictly smaller than \( u_i \).
An interval support for a value \( v \in \text{dom}(X_i) \) with respect to a constraint \( C(X_1, \ldots, X_n) \) is a tuple \( t \) satisfying three conditions for \( j \in 1..n \): 1) \( l_j \leq t[j] < u_j \), 2) \( t[j] = v \) and 3) the tuple \( (t[1], \ldots, t[n]) \) satisfies the constraint \( C \). A constraint is bounds consistent if \( l_i \) and \( u_i - 1 \) have an interval support for all \( i \in 1..n \). Enforcing bounds consistency on a constraint consists of increasing the lower bounds and decreasing the upper bounds of the domains until all bounds have an interval support. Example 1 shows the result of enforcing bounds consistency on the Multi-INTER-DISTANCE constraint.

**Example 1** We consider the constraint

\[ \text{MULTI-INTER-DISTANCE}([X_1, X_2, X_3, X_4, X_5], m, p) \]

with \( m = 2 \), \( p = 3 \), and the following domains.

- \( \text{dom}(X_1) = [7, 9] \)
- \( \text{dom}(X_2) = [2, 4] \)
- \( \text{dom}(X_3) = [4, 7] \)
- \( \text{dom}(X_4) = [2, 7] \)
- \( \text{dom}(X_5) = [3, 5] \)

The domains are semi-open intervals which implies that the value 1 belongs to the domain of \( X_1 \) but the value 9 does not belong to the domain of \( X_1 \).

Enforcing bounds consistency on the Multi-INTER-DISTANCE shrinks the domains as follows.

- \( \text{dom}(X_1) = [8, 9] \)
- \( \text{dom}(X_2) = [2, 3] \)
- \( \text{dom}(X_3) = [5, 7] \)
- \( \text{dom}(X_4) = [5, 7] \)
- \( \text{dom}(X_5) = [3, 4] \)

**Testing for Satisfaction in Polynomial Time**

The Multi-INTER-DISTANCE has a strong connection to scheduling problems. Consider the constraint \( \text{MULTI-INTER-DISTANCE}([X_1, \ldots, X_n], m, p) \) where the domain of the variable \( X_i \) is the semi-open interval \([l_i, u_i]\). The variable \( X_i \) can be considered as the starting time of a task whose processing time is \( p_i \), whose release time is \( l_i \), and whose deadline is \( u_i + p - 1 \). A total of \( m \) identical resources execute the tasks concurrently without preemption. The Multi-INTER-DISTANCE constraint is satisfiable if and only if there exists a schedule.

This scheduling problem can be solved in polynomial time. The best algorithm (López-Ortiz & Quimper 2011) so far has a worst-case time complexity of \( O(n^2 \min(1, \frac{p}{m})) \). The algorithm finds a valid schedule by computing a shortest path in a scheduling graph (Dürr & Hurand 2009). This section provides a description of this graph and its properties. The scheduling graph is the key concept on which the filtering algorithm is based.

Let \( l_{\text{min}} = \min(X_i) \) and \( u_{\text{max}} = \max(X_i) \) be the smallest lower bound and the greatest upper bound of a variable domain. The scheduling graph \( G \) has a node \( v \) for every integer \( l_{\text{min}} \leq v \leq u_{\text{max}} \). There is a forward edge of weight \( m \) from node \( v \) to node \( v + p \) for all \( l_{\text{min}} \leq v \leq u_{\text{max}} - p \). For every pair of lower bound and upper bound \( l_i < u_j \), there is a backward edge \((u_j, l_i)\) of weight \(-\{k | l_k \leq l_i \land u_k \leq u_j\}\). The absolute value of the weight of the backward edge \((u_j, l_i)\) is the number of variables whose domain is contained in the interval \([l_i, u_j]\). A backward edge can have a null weight. There is a null edge from any node \( v + 1 \) to node \( v \) of weight 0 for all \( v \in [l_{\text{min}}, u_{\text{max}}] \). Finally, there is an edge \((l_{\text{min}}, u_{\text{max}})\) of weight \( n \) where \( n \) is the arity of the Multi-INTER-DISTANCE constraint.

Table 1 shows the weight matrix of the scheduling graph of Example 1. Empty entries indicate the lack of an edge between nodes \( \alpha \) and \( \beta \).

Theorem 1 (López-Ortiz & Quimper 2011) The scheduling problem has a solution if and only if the scheduling graph has no negative cycles.

Theorem 2 (López-Ortiz & Quimper 2011) Testing whether there is a negative cycle in the scheduling graph can be done in \( O(n^2 \min(1, \frac{p}{m})) \) time.

Theorems 1 and 2 allow to test the satisfiability of the constraint in quadratic time. In the next sections, we reuse this result to design an efficient filtering algorithm.

**Conditions to Maintain Bounds Consistency**

Our filtering algorithm detects forbidden sets of values that cannot be assigned to a set of variables. For the ALL DIFFERENT constraint, these sets are called Hall intervals (Leconte 1996). For the Multi-INTER-DISTANCE, we call them forbidden regions. We present lemmas that detect these forbidden regions.

To test whether an interval \([a, b]\) is a forbidden region to which a variable \( X_i \) is subject, one can modify the domain of \( X_i \) to be \([a, b]\) and test the satisfiability of the problem. If the scheduling graph of the transformed problem has a negative cycle, then \([a, b]\) is a forbidden region for \( X_i \).

We define the altered scheduling graph \( G' \) like the scheduling graph with one exception, we alter the upper bound of the domain of \( X_i \) such that the new domain becomes \([l_i, v]\). If \( G' \) has a negative cycle, the constraint has no solution and we conclude that \( X_i \geq v \). Table 1 gives the weight matrix of the graph \( G \). Decrementing bold entries by one results in the altered scheduling graph \( G'' \). In the graph \( G'' \), the edges \((5, 2)\) and \((2, 5)\) form a cycle of weight -1 which proves that \( X_3 \geq 5 \). The following theorem shows how a forbidden region for one variable can also be a forbidden region for another variable.
**Theorem 3** Let $X_i$ and $X_j$ be two variables whose domains satisfy $u_i \leq u_j$. If the values in $[l_i, v]$ have no interval support in $\text{dom}(X_j)$, then they do not have an interval support in $\text{dom}(X_j)$ either.

**Proof:** We prove the contraposition: if there exists a value $a \in [l_i, v)$ that has an interval support in the domain of $X_j$, then there exists a value $b \in [l_i, v)$ that has an interval support in the domain of $X_i$. Suppose there exists an interval support $t$ such that $[t][j] \in [l_i, v)$. We want to prove that there exists an interval support $t'$ such that $t'[i] \in [l_i, v)$. Two cases can occur. If $t[i] \leq t[j]$ then the inequalities $l_i \leq t[i] \leq t[j] < v$ hold and $t[i] \in [l_i, v)$. The theorem holds with $t' = t$. However, if $t[i] > t[j]$ then the inequalities $l_j \leq t[i] < t[j] \leq u_i \leq u_j$ hold. We can permute the values $t[i]$ and $t[j]$ to obtain the support $t'$. We have $t'[i] = t[j] \in [l_i, v)$ and $t'[j] = t[i] \in [l_j, u_j)$ hence $t'$ is a valid support. \qed

In Example 1, the graph $G_3^5$ has a negative cycle which proves that $(4, 5)$ is a forbidden region for $X_3$. Theorem 3 also makes $(4, 5)$ a forbidden region for the variable $X_4$.

The distance matrix $D_G$ of a graph $G$ is a square matrix such that $D_G(a, b)$ is the shortest distance between node $a$ and node $b$ in graph $G$. This matrix exists only if there are no negative cycles in the graph $G$. When comparing the scheduling graph $G$ of Example 1 and the altered scheduling graph $G_3^5$, one sees that the weights of a subset of the edges are decremented by one. This can only lead to shorter paths in $G_3^5$ than in $G$. Lemma 1 captures this property.

**Lemma 1** Let $G$ be the scheduling graph of a problem where the domains are given by the intervals $[l_i, u_i)$ for $1 \leq i \leq n$. Let $G'$ be the scheduling graph of the same problem except that the domain of $X_i$ is changed to $[l'_i, u'_i)$ where $l_i \leq l'_i < u'_i \leq u_i$. Thus $D_G(a, b) \geq D_{G'}(a, b)$ holds for all pairs of nodes $(a, b)$.

**Proof:** The weight of a backward edge $(u_j, l_k)$ is minus the number of variable domains contained in the interval $[l_k, u_j)$. If the domain of a variable is shrunk, the weight of the backward edges can be decremented by one or remain unchanged. These changes to the scheduling graph can only favor shorter paths.

However, the backward edges outgoing from $u_i$ or incoming to $l_i$ may not exist in $G'$ as $u_i$ and $l_i$ may not be domain bounds after shrinking the domain of $X_i$. Let $(u_f, l_e)$ be a backward edge in $G$ such that $f = i \lor e = i$. We prove that the edge $(u_f, l_e)$ in $G$ can be replaced by an equivalent path in $G_i$. Let $u'_f = \max\{u_k | u_k \leq u_f \land k \neq i\} \cup \{u'_i\}$ and let $l'_e = \min\{l_k \geq l_e \land k \neq i\} \cup \{l'_i\}$. The weight of the backward edge $(u'_f, l'_e)$ in $G'$ is the same as the weight of the backward edge $(u_f, l_e)$ in $G$. Moreover, we have $l_e \leq l'_e$ and $u'_f \leq u_f$. Any path in $G$ passing by the edge $(u_f, l_e)$ can be replaced by a sequence of null edges from $u_f$ to $u'_f$, then passing by the edge $(u'_f, l'_e)$, and completing with a sequence of null edges from $l'_e$ to $l_e$. This path in $G_i$ has the same weight as the edge $(u_f, l_e)$ in $G$. \qed

Let $U = \{u_i | i \in 1..n\}$ be the set of the domain upper bounds and let $u^* = \min\{u \in U | u > l_i\}$ be the smallest upper bound that does not make the interval $[l_i, u^*)$ empty. The altered scheduling graph $G_i^{u^*}$ gives information about how the lower bound of $X_i$ can be filtered. If $G_i^{u^*}$ has a negative cycle, then $X_i \geq u^*$ and the lower bound $l_i$ can be safely increased to $u^*$. If $G_i^{u^*}$ has no negative cycle, then Theorem 4 and Theorem 5 indicates how to prune the lower bound of variable $X_i$.

**Theorem 4** Let $X_i$ be a variable subject to a *multi-inter-distance* constraint. Let $u^*$ be the smallest upper bound that is greater than $l_i$ and let $G_i^{u^*}$ be its associated altered scheduling graph. Suppose this graph has no negative cycle. Let $t$ be the largest value such that the distance $D_{G_i^{u^*}}(l_i, t)$ is null. Values smaller than $t$ in the domain of $X_i$ have no interval support.

**Proof:** Since $G_i^{u^*}$ has no negative cycles, there exists at least one solution with $X_i \in [l_i, u^*)$ where $u^* = \min\{u_k | u_k > l_i\}$. Let $t$ be the largest value for which the shortest distance in $G_i^{u^*}$ from $l_i$ to $t$ is null. We prove by contradiction that $t < u^*$. Suppose $t \geq u^*$. The weight of the edge $(u^*, l_i)$ is at most -1 since it fully contains the altered domain of $X_i$. Contradictorily, there is a negative cycle in $G_i^{u^*}$ starting from $l_i$, going to $t$ through a path of weight zero (by definition of $t$), passing by the null edges $(t, t - 1), (t - 1, t - 2), \ldots, (u^* + 1, u^*)$ with weight zero, and then going back to $l_i$ using the edge $(u^*, l_i)$ with weight at most -1. Therefore, $t < u^*$. Knowing that $t < u^*$, we construct the altered scheduling graph $G_i^{u^*}$ using the original variable domains except for $X_i$ for which we use the domain $\text{dom}(X_i) = [l_i, t)$. The edge $(t, l_i)$ has a negative weight since the interval $[l_i, t)$ contains the domain of $X_i$. The distance from $l_i$ to $t$ is null in $G_i^{u^*}$ and, by Lemma 1, no greater than 0 in $G_i^{u^*}$. Therefore, there is a negative cycle in $G_i^{u^*}$ passing by the edge $(t, l_i)$ which implies that no values in $[l_i, t)$ have an interval support in $\text{dom}(X_i)$. \qed

To illustrate Theorem 4, consider the variable $X_1$ in Example 1. The smallest upper bound that is greater than the lower bound 7 is $u^* = 9$. The altered scheduling graph $G_1^9$ is identical to the scheduling graph $G$. The path $(7, 2), (2, 5), (5, 8)$ has a null weight in $G_1^9$. By Theorem 4, there is no valid assignment with $X_1 < 8$.

Theorem 4 shows there is no interval support $X_i \in [l_i, t)$. Theorem 5 shows that there is an interval support for $X_i = t$.

**Theorem 5** Let $X_i$ be a variable subject to a *multi-inter-distance* constraint. Let $u^*$ be the smallest upper bound that is greater than $l_i$ and let $G_i^{u^*}$ be its associated altered scheduling graph. Suppose this graph has no negative cycle. Let $t$ be the largest value such that the distance $D_{G_i^{u^*}}(l_i, t)$ is null. The value $t$ has an interval support in the domain of $X_i$.

**Proof:** We construct the scheduling graph $G_i^{u^*}$ using the original variable domains except for $X_i$ for which we use the domain $[l_i, t + 1)$. If one proves that $G_i^{u^*}$ has
no negative cycle, then one proves there is a solution with 
\(X_t \in [l_t, t + 1]\). Theorem 4 ensures that \(X_t \geq t\) leaving 
\(X_t = t\) as the unique valid assignment for the variable \(X_t\). 
The graph \(G_i^{t+1}\) has no negative cycles when \(t + 1 = u^*\). 
Indeed, in that specific case, the graphs \(G_i^t\) and \(G_i^{u^*}\) 
are by construction identical. From the proof of Theorem 4, we 
know that \(t \leq u^*\). We therefore need to prove that \(G_i^{t+1}\) has 
no negative cycles when \(t + 1 < u^*\).

Let \(u_q\) be the greatest upper bound that is strictly smaller 
than \(u^*\). By construction, there is no upper bounds greater 
than \(l_t\) and smaller than \(u^*\), thus \(u_q < l_t\). The null edges 
form a path from \(l_t\) to \(u_q\) which implies \(D_{G_i^{t+1}}[l_t, u_q] \leq 0\).

Consider any lower bound \(l_p\) that is smaller than or equal to 
\(l_t\). The domain \(\text{dom}(X_i) = [l_t, t + 1]\) is the only one that 
is not contained in the interval \([l_p, u_q]\) but is contained in the 
interval \([l_p, t + 1]\), thus \(-w(u_q, l_p) = -w(t + 1, l_p) - 1\).

The graphs \(G_i^u\) and \(G_i^{t+1}\) are very similar. They only 
differ by the additions of backward edges \((t + 1, l_p)\) for all 
lower bound \(l_q \leq l_t\). It is therefore sufficient to prove that 
any cycle passing by these edges has a non-negative weight.

Since the addition of the edges leaving \(t + 1\) does not 
affect the paths leading to \(t + 1\), we have \(D_{G_i^{t+1}}[l_t, t + 1] = D_{G_i^u}[l_t, t + 1]\). By the definition of \(t\), we obtain 
\(0 < D_{G_i^u}[l_t, t + 1] = D_{G_i^{t+1}}[l_t, t + 1]\). The consequence of 
this inequality is that any path going from \(l_t\) to \(t + 1\) has 
a positive weight and in particular, a path going from \(l_t\) to 
\(t + 1\) passing by the edge \((u_q, l_p)\) has positive weight.

\[
0 < D_{G_i^{t+1}}[l_t, u_q] + w(u_q, l_p) + D_{G_i^{t+1}}[l_p, t + 1]
\]  \hspace{1cm} (1)

By substituting \(-w(u_q, l_p) = -w(t + 1, l_p) - 1\) and 
\(D_{G_i^{t+1}}[l_t, u_q] \leq 0\) in (1) we prove that all cycles passing 
by the edge \((t + 1, l_p)\) are non-negative.

\[
0 < 0 + w(t + 1, l_p) + 1 + D_{G_i^{t+1}}[l_p, t + 1]
\]  \hspace{1cm} (2)

\[
0 \leq w(t + 1, l_p) + D_{G_i^{t+1}}[l_p, t + 1]
\]  \hspace{1cm} (3)

In Example 1, the path \((7, 2), (2, 5), (5, 8)\) in \(G_i^2\) has a null 
weight which certifies that there exists an interval support 
for 8 in the domain of \(X_1\). This interval support is \(t = [8, 2, 5, 6, 3]\).

A Filtering Algorithm Achieving Bounds

Consistency

The filtering algorithm for the MULTI-INTER-DISTANCE is a 
direct application of Theorem 3, Theorem 4, and Theorem 5. The algorithm on Figure 1 processes the variables in 
non-decreasing order of domain upper bounds. When 
processing \(X_t\), the algorithm updates the lower bound \(l_t\) ac-
cording to previously discovered forbidden regions. Then 
it computes the value \(u^*\) that is the smallest domain upper 
bound greater than \(l_t\). Based on this value, the algorithm 
tests whether the scheduling graph \(G_i^u\) has a negative cy-
cle. If so, the algorithm stores in the data structure \(F\) the 
newly detected forbidden region \([l_t, u^*]\). Because the algo-
rithm processes variables in non-decreasing order of upper 

bounds, Theorem 3 ensures that the interval \([l_t, u^*]\) is a for-
bidden region for all unprocessed variables. On its next iter-

ation, the lower bound \(l_t\) is increased to avoid all forbidden 
regions, including the newly discovered one. This process 
continues until the scheduling graph \(G_i^{u^*}\) contains no nega-
tive cycles.

When the scheduling graph \(G_i^{u^*}\) contains no negative cy-
cles, Theorem 4 and Theorem 5 apply. The algorithm com-
putes the shortest path from node \(l_t\) to all the other nodes 
and finds the node \(t\) which is the largest one whose distance 
from node \(l_t\) is null. From Theorem 4, we know that val-
ues smaller than \(t\) have no interval support in the domain of 
the current variable. The algorithm removes them from the 
domain by increasing the value of \(l_t\). Finally, Theorem 5 
guarantees that the lower bound of each variable domain has 
an interval support upon completion of the algorithm.

Computing the single-source shortest path in the schedul-
ging graph should be done with care. Indeed, the schedul-
ing graph has as many nodes as the number of values in 
the domains. These domains can be very large especially in 
scheduling problems where domains represent time 
intervals. (López-Ortiz & Quimper 2011) showed how to 
compute the shortest path from the right-most node to all 
the other nodes in \(O(n^2 \min(1, \frac{1}{m}))\) steps which is strongly 
polynomial and invariant in the cardinality of the variable 
domains. The algorithm is an adaptation of the Bellman-
Ford algorithm (Cormen et al. 2001) which initializes a dis-
tance vector that keeps track of the distances from the node 
\(l_t\) to all the other nodes. Since the right-most node can reach 
all the other nodes via the null edges, the distance vector is 
initialized to zero and as new paths are explored, the dis-
tance vector is updated with smaller values. To compute 
the shortest path from \(l_t\) to all the other nodes, the distance 
vector should be initialized to zero for all the nodes smaller 
than or equal to \(l_t\) and \(n\) for all the nodes that are greater 
than \(l_t\). Indeed, any node \(t\) can be reached by going to \(l_{min}^t\) 
through the null edges, then going to \(u_{max}\) using the edge 
\((l_{min}, u_{max})\), and finally using the null edges to go to \(t\). This
The filtering algorithm is therefore $O(n^2 \min(1, \frac{p}{m}))$.

The computation of shortest paths dominates the algorithm's complexity.

**Lemma 2** The algorithm PruneLowerBounds performs at least $n$ and at most $3n - 1$ shortest path computations where $n$ is the number of variables.

**Proof:** Computing the shortest path of an altered scheduling graph leads to two possible outcomes: the graph has negative cycles or it does not. If the graph has no negative cycles, the repeat loop terminates. This occurs exactly $n$ times, once for each variable. If the graph has negative cycles, the algorithm loops and creates the forbidden region $[l_i, u^*]$. The value $u^*$ is a domain upper bound. Each time a new forbidden region is created, one of two events can occur: 1) a domain upper bound becomes for the first time the upper open bound of a forbidden region 2) a domain upper bound gets included in forbidden region. These two events can occur only once for each upper bound at the exception of the largest upper bound $u_{\text{max}}$ for which only the first event can occur. Therefore, the algorithm creates at most $2n - 1$ forbidden regions and performs at most $3n - 1$ shortest path computations.

The shortest path problem is solved in $O(n^2 \min(1, \frac{p}{m}))$ steps when using the algorithm of (López-Ortiz & Quimper 2011) and modifying the initial state of the distance vector as described above. The total running time complexity of the filtering algorithm is therefore $O(n^3 \min(1, \frac{p}{m}))$ which is never more than $O(p^3)$.

Pruning the upper bounds can be done by pruning the lower bounds in a symmetric problem where dom($X_i^a$) = $[-u_i, -l_i]$. When pruning the lower bounds, the value $-u_i$ is increased which is equivalent to decrease the upper bound $u_i$ in the original problem.

## Experiments

We experiment the Multi-Inter-Distance on the runway scheduling problem as presented in (Artiouchine & Baptiste 2005). This problem consists of determining the order in which $n$ airplanes should land on a runway. We consider an airport with $m$ runways allowing simultaneous landings. Each airplane labeled from 1 to $n$ has multiple disjoint time windows $[a_i^1, b_i^1], \ldots, [a_i^k, b_i^k]$ in which it is in position to land. The goal is to make each airplane land within one of its time windows while maximizing the time gap $p$ between each landing on a same runway.

We model the problem with two variables per airplane. The variable $S_i$ defines at what time the airplane $i$ lands. The variable $W_i \in [1, k_i]$ defines in which time window the airplane $i$ lands. The two variables are connected with the constraints $W_i \leq w \iff S_i \leq b_i^w$ and $W_i \geq w \iff S_i \geq a_i^w$. Finally, there is a Multi-Inter-Distance posted on the vector of variables $S$ with fixed parameter $p$ and $m$. We solve the problem for $p = 1, 2, 4, 8, \ldots$ until the problem becomes infeasible. We then perform a binary search between the largest $p$ for which there exists a solution and the smallest $p$ for which we detect infeasibility. We branch on the variables $W_i$ followed by the variables $S_i$.

For $m = 1$, we use the benchmark described as the second set in (Artiouchine & Baptiste 2005). There are 64 instances for each $n \in \{15, 30, 45, 60, 75, 90\}$. The number of time windows per airplane randomly varies from 1 to 5.

We generate instances for $m = 2$ and $m = 3$ by merging instances from the original benchmark. As a rule, we merge instances having the same size of time windows or the same gap between the time windows. Merged instances also have a similar number of airplanes. As $m$ increases, we obtain instances with more airplanes. We implement our solution (denoted MID) using the Choco Solver and compare it against two implementations of the cumulative constraint that the solver provides. The first implementation performs an overload checking (denoted OC) in $O(n \log n)$ using a $\Theta$-tree as designed by (Vilím, Barták, & Čepek 2004). The second implementation (denoted MVH) is an implementation of the edge-finder (Mercier & Hentenryck 2008) in $O(n^2)$. Experiments are run arbitrarily on an Opteron 275 2.2 GHz and an Opteron 2376 2.3 GHz. Running times may vary depending on which processor executes the program.

Figure 1 shows that MID solves more problems in a given time for $m \in \{1, 2, 3\}$ than MVH and OC. The difference in performance becomes more prominent as $m$ increases. For $m = 3$, MID solves 134 instances in 20 minutes, MVH solves 3 instances, and OC solves none. Table 2 shows that MID solves the problem with significantly fewer backtracks. MVH performs fewer backtracks as $n$ increases indicating that the filtering gets slower and fewer nodes are visited within 20 minutes.

Conclusion
We introduced the MULTI-INTER-DISTANCE constraint. We made the connection between this constraint and the properties of the shortest paths in the scheduling graph. We applied these properties in the design of the first filtering algorithm achieving bounds consistency. This new constraint is very successful at solving large instances of the runway scheduling problem. The theorems we proved about the MULTI-INTER-DISTANCE constraint may lead in the future to the design of better filtering algorithms for related constraints such as the INTER-DISTANCE and the CUMULATIVE constraints.

Acknowledgments
We would like to thank Arnaud Malapert for his support with the Choco solver and the reviewers for helping us simplifying the proof of Theorem 3. This research is supported by a NSERC Discovery Grant.
